# $\Sigma^0$ and $\overline{\Sigma}^0$ Production in pp Collisions at $\sqrt{s}=7$ TeV

PC: A. Borissov, A. Badala, I.-K.Yoo IRC:

ALICE Collaboration\*

6 Abstract

The first measurements of  $\Sigma^0$  and  $\overline{\Sigma}^0$  baryons' transverse momentum  $(p_T)$  spectra, integrated yields and mean  $p_T$  in pp collisions at the LHC are reported. The  $\Sigma^0$  ( $\overline{\Sigma}^0$ ) signal is reconstructed via the  $\Lambda$  ( $\overline{\Lambda}$ ) +  $\gamma$  decay channel by invariant mass analysis. The  $\Lambda$  ( $\overline{\Lambda}$ ) baryon is reconstructed by its decay into  $p + \pi^-$  ( $\overline{p} + \pi^+$ ), while the photon is detected exploiting the unique capability of the ALICE detector to measure low energy photons via conversion into  $e^+e^-$  pairs. The yield of  $\Sigma^0$  is compared to that of the  $\Lambda$  baryon, which has the same quark content but different isospin. These data contribute to the understanding of hadron production mechanisms and provide a reference for constraining QCD-inspired models and tuning Monte Carlo event generators such as PYTHIA.

### 28 1 Introduction

The study of strange baryons and their resonances in proton-proton collisions provides a reference for 29 tuning QCD inspired event generators and contributes to the understanding of strangeness production 30 mechanisms. Colliding projectiles initially contain no strange valence quarks indeed and therefore all 31 strange particles are created in the collisions. In particular,  $\Sigma$  measurements can help to understand 32 production mechanisms of baryons with non-zero isospin. These are an important complement of the 33 Lambda data as these particles have similar mass  $(m_{\Sigma} - m_{\Lambda} \sim 77 \text{ MeV})$  and equal quark content (uds), 34 but different isospin value  $(I_{\Lambda} = 0, I_{\Sigma} = 1)$  [1]. Furthermore a yield ratio of  $\Sigma^0$  to  $\Lambda$  can provide a hint to 35 understand a charge and/or isospin independency of the  $\Sigma^{\pm}$  and  $\Sigma^{0}$  due to the same  $I(J^{p})$ , analogy to the 36 yield ratio of  $\pi^0/\eta$  [2].

All  $\Lambda$  ( $\overline{\Lambda}$ ) measurements include a feed-down from  $\Sigma^0$  ( $\overline{\Sigma^0}$ ). In fact, the main decay of the  $\Sigma^0$  ( $\overline{\Sigma^0}$ ) is the electromagnetic one ( $\Sigma^0$  ( $\overline{\Sigma^0}$ )  $\to \Lambda$  ( $\overline{\Lambda}$ ) +  $\gamma$ ) with a 100 % branching ratio. Usually this feed-down contribution is not considered for the  $\Lambda$  ( $\overline{\Lambda}$ ) spectrum and as a consequence, model predictions for  $\Lambda$  ( $\overline{\Lambda}$ ) baryons are compared with data including secondary  $\Lambda$  ( $\overline{\Lambda}$ ) originated from  $\Sigma^0$  ( $\overline{\Sigma^0}$ ) [?]. Thus the measurement of the  $\Sigma^0$  ( $\overline{\Sigma^0}$ ) spectrum enables us to estimate the contribution of the secondary  $\Lambda$  ( $\overline{\Lambda}$ ) in the hyperon spectrum. Furthermore, the  $\Sigma^0$  production rates can be also an important measure to correct the  $p_T$  spectra of proton, pion and photon with taking into account the feed-down contributions from  $\Sigma^0$  [?].

Comparison of hyperon data with models as PYTHIA [3] and EPOS [4] permits to investigate their production mechanism. In particular, at LHC energies a significant disagreement was observed in  $p_T$  spectrum of  $\Lambda$  between PYTHIA6 Perugia 2011 [3] predictions and measurements of ALICE [5] and AT-LAS [6] experiments. In this respect, the measurement of the  $p_T$  spectrum of  $\Sigma^0$  and the ratio of  $\Sigma^0$  to  $\Lambda$  at the LHC energy are fundamental for the tuning of the models and to understand the hadronic mechanism processes.

In this paper the first measurement of the  $\Sigma^0$  ( $\overline{\Sigma^0}$ ) transverse momentum spectrum and its integrated yield measured at mid-rapidity with ALICE detector in inelastic pp collisions at  $\sqrt{s}$  =7 TeV are presented and compared with the  $\Lambda$  results in the same collisions. This enriches the existing data set limited until now to low energy collisions results.

## 56 2 Experimental setup and event selection

Since a complete and detailed description of the ALICE detector and of its performance during the LHC Run 1 (2010-2013) can be found in refs [7, 8], we briefly outline only the sub-detectors utilized for  $\Sigma^0$  analysis: Inner Tracking System (ITS), the Time Projection Chamber (TPC) and the VZERO-trigger detectors below.

Vertex reconstruction and tracking in the central-barrel and charged-hadron identification are performed 61 with the Inner Tracking System (ITS) [7] and the Time-Projection Chamber (TPC) [9], which are located 62 inside a solenoidal magnet providing a magnetic field of 0.5 T parallel to the LHC beam axis. The ITS 63 is composed of six cylindrical layers of silicon detectors, located at radii between 4 and 43 cm from the nominal beam axis with covering a pseudo-rapidity range of  $|\eta| < 0.9$  and the full azimuth. The two 65 innermost layers consist of Silicon Pixel Detectors (SPD), the two intermediate layers of Silicon Drift 66 Detectors (SDD) and the two outermost layers of Silicon Strip Detector (SSD). The spatial resolution 67 of the ITS enables measuring the distance of closest approach (DCA) of tracks to the primary vertex 68 with a resolution better than 75  $\mu$ m in the transverse plane for  $p_T > 1$  GeV/c in pp collisions [10]. The 69 Time Projection Chamber (TPC) is a large (90 m<sup>3</sup>) cylindrical gaseous detector filled with a mixture 70 of Ne/CO<sub>2</sub> /N<sub>2</sub> (85.7/9.5/4.8%). It covers radially between 85 and 250 cm from the beam axis and a 71 pseudo-rapidity range of  $|\eta| < 0.9$  over the full azimuth, and provides track reconstruction with up to

159 space points, with a spatial resolution of 500  $\mu$ m along the beam direction and in the transverse direction for tracks with  $\eta=0$  [9]. In addition, it enables particle identifications via the measurement of 74 the specific ionization energy loss (dE/dx) with a resolution of approximately 5.2% in pp collisions [8]. 75 The data sample analyzed in this paper was recorded during the LHC pp run at  $\sqrt{s} = 7$  TeV in 2010 76 (only ? or - 2013?) using a magnetic field of 0.5 T, with both field polarities and a minimum-bias (MB) 77 trigger. The MB trigger required a single hit in the SPD detector or in one of the two VZERO counters, 78 i.e. at least one charged particle anywhere in the  $\sim$ 8 units of pseudo-rapidity covered by these detectors. In addition, a coincidence was required with signals from two beam pick-up counters, one on each side 80 of the interaction region, indicating the passage of proton bunches. The trigger selection efficiency for 81 inelastic collisions was estimated to be 85.2 % with a +6.2 % and ?3 % uncertainty. While SPD covers 82  $|\eta| < 2.0$ , the two VZERO detectors, each consisting of scintillator tiles, are installed on both sides of 83 the interaction point and cover -3.7 <  $\eta$  < -1.7 and 2.8 <  $\eta$  < 5.1 [2, 11, 12]. 84 These VZERO detectors are used for triggering (Is it the same to  $f_{inel}$ , which must be same to the  $MB_{OR}$ 85 = INEL?) and for rejecting beam-gas interactions (What is it?). Due to the low luminosity of this (Where 86 can I find it?) data taking a high-efficiency (85.2 % [13]) MB trigger (It is NOT the MB, but MB<sub>OR</sub>!) 87 was used. The contamination from beam-induced background was reduced to a negligible level with the 88 help of the timing information of the VZERO counters and by a cut on the position of the primary vertex 89

Events used for the data analysis are further required to have just one reconstructed primary vertex (PV), events containing more than one distinct vertex are tagged as pileup and are discarded. The PV is determined by tracks reconstructed in the ITS and Time Projection Chamber (TPC), and track segments in the SPD [8]. MB events are selected when the PV is positioned along the beam axis within  $\pm 10$  cm from the center of the ALICE detector. The vertex reconstruction efficiency is 92.8 % [12].

reconstructed by the SPD, as discussed in detail in [8] (Is this related to Nofflinetrigger? But how?). The

probability of collision pileup per triggered event was below 3 % [12](How is it treated? Is it also taken

into account for the final  $N_{norm}$ , but how?. A total amount of about 500 million MB events has been

```
Question: in [12], MB_{OR} = INEL = at least one hit at SPD OR one of V0s NSD = an additional condition of coincidence of two V0s = MB_{AND} What was used? MB_{OR} or MB_{AND}?

MB_{AND}/MB_{OR} = 0.873 in [10, 13] f_{inel} = trigger efficiency for INEL = 87\%, f_{vtx} = vertex reconstruction within \pm 10cm = 88\%

What is then N_{in} and N_{offilinetrigger}? Nowhere I can find it.

what is the relation between N_{norm} and N_{MB}?
```

## 3 Data analysis

utilized for the analysis.

106

 $\Sigma^0$  were reconstructed by its electromagnetic decay ( $\Sigma^0(\overline{\Sigma^0}) \to \Lambda(\overline{\Lambda}) + \gamma$ ) which has a 100 % branching 107 ratio. The main feature of this decay is the low energy of the energy of the emitted photon  $\approx 100 \text{ MeV}$ 108 (any reference? Why is it relevant?). The Photon Conversion Method (PCM) in the central tracking 109 system was used for photon identification employing the ITS and the TPC [2, 8, 14]. It reconstructs and 110 identifies the vertices  $(V0_{\gamma})$  of photon conversions to  $e^+e^-$  pair generated in the material of the inner 111 detectors. For ALICE detector the probability of photon conversion in the central tracking system is 112 about 0.08 and the reconstruction efficiency is about 0.67 [2]. Reliability of the method is based on the 113 good agreement of the actual material budget and the simulated one [8]. Then both the decay products 114 of the  $\Sigma^0$  were identified as secondary vertices (V0):  $V0_{\Lambda}$  of the weak decay  $\Lambda(\overline{\Lambda}) \to p(\overline{p}) + \pi^+(\pi^-)$ 115 and  $V0_{\gamma}$  of the photon conversion identified during tracking procedure as secondary vertices. 116

In the PCM analysis, photons are reconstructed as vertices  $(V0_{\gamma})$  of electron and positron pair [2, 14–

16]. The tracks for  $e^-$  ( $e^+$ ) candidates are basically selected if: (1)  $|\eta| < 0.9$ , (2)  $p_T > 0.05$  GeV/c, (3) the ratio of the number of reconstructed to findable TPC clusters is larger than 0.35. For the particle identification of  $e^-(e^+)$  tracks, the specific energy loss of electrons (positrons) in the TPC was required to be within a band between  $-6\sigma_e$  and  $7\sigma_e$  around the average dE/dx-value depending on  $p_T$ , where  $\sigma_e$  is a standard deviation of the measured dE/dx distribution for  $e^-(e^+)$ . In addition, in order to reduce pion and kaon contaminations by rejecting the tracks with  $|dE/dx| < 1\sigma_{\pi,K}$  for  $p_T < 0.5$  GeV/c, where  $\sigma_{\pi,K}$  are the standard deviations of measured dE/dx distribution for pions ( $\sigma_{\pi}$ ) and kaons ( $\sigma_{K}$ ), respectively.

To select photons among all secondary vertices, further selection was performed on the level of the reconstructed V0 $_{\gamma}$  [2, 14]. To remove  $\pi^0$  and  $\eta$  meson Dalitz decays, the transverse distance (why only R $_T$ ?) of V0 $_{\gamma}$  from PV have to be larger than 5 cm and smaller than 180 cm due to the V0 reconstruction procedure. Finally, the photons only with  $p_T > 0.020$  GeV/c and  $|\eta| < 0.9$  are accepted. Additional cuts of  $q_T = p_e \sin \Theta_{\gamma,e} < 0.06$  GeV/c, where  $p_e$  is electron momentum and  $\Theta_{\gamma,e}$  is the angle between  $\gamma$  momentum ( $p_{\gamma}$ ) and electron momentum [17], and  $\Psi_{pair} < 0.20$ , where  $\Psi_{pair}$  is the angle between the plane perpendicular to the magnetic field (x-y) plane and the plane of the  $e^-(e^+)$  pair [16] are applied for increasing the purity of  $e^-(e^+)$  from  $\gamma$ .

To select  $\Lambda$  from  $\Sigma^0$ , the similar selection-criteria of the secondary vertex (V0 $_{\Lambda}$ ) used in [5, 18, 19] with exploiting the weak decay topology of  $\Lambda$  ( $\overline{\Lambda}$ )  $\rightarrow p\pi^-(\bar{p}\pi^+)$  (branching ratio of 63.9% and decay length of  $c\tau=7.89$  cm [1]), is applied. The distance of closest approach (DCA) between positive (negative) tracks from V0 $_{\Lambda}$  and PV was selected to be larger than 0.06 cm, and the cosine of the pointing angle  $\Theta$  between the sum of daughter momenta and the line that connects the PV and V0 $_{\Lambda}$ , was requested to be greater than 0.993. The transverse distance between V0 $^{\Lambda}$  and PV is requested to be between 0.5 and 180 cm. An Armenteros-Podolanski cut on  $\Lambda$ : 0.01 <  $\alpha$  < 0.17 and 0.2 <  $|q_T|$  < 0.9 was applied, where  $\alpha_{\Lambda} = |\frac{p_l^p - p_l^n}{p_l^p + p_l^n}|$ , where  $p_l^i$  is the longitudinal momentum of a particle i (p or  $\pi$ ) with respect to the  $\Lambda$  momentum direction,  $q_T$  corresponds to transverse momentum of proton with respect to the  $\Lambda$  momentum. Additionally a lifetime cut is applied as.... The  $\Lambda$  invariant mass ( $M_{p\pi}$ ) was selected within the interval of 1.110 <  $M_{p\pi}$  < 1.120 GeV/ $c^2$  to reduce the amount of combinatorial background of  $\Sigma^0$  invariant mass peak. Note, the nominal  $\Lambda$  mass ( $m_{\Lambda}$ ) with its uncertainty is  $m_{\Lambda} = 1115.683 \pm 0.006$  [1].

	γ	Λ	$\Sigma^0$
$p_{\mathrm{T}}$	> 0.020	> 0.4	> 1.1
$ \eta $	< 0.9	< 0.5	< 0.5
$\alpha$	-	(0.01, 0.17)	> 0.6
$q_{\mathrm{T}}$	< 0.06	(0.2, 0.9)	< 0.12

**Table 1:** The final selection criteria of  $\Sigma^0$  and its daughter particles.

In order to enhance the significance of the  $\Sigma^0$  signal, softer cuts on  $\Lambda$  selection than those used in  $\Lambda$  [18, 19] and the additional phase-space cuts on  $\Sigma^0$  as  $\alpha = |\frac{p_l^{\gamma} - p_l^{\Lambda}}{p_l^{\gamma} + p_l^{\Lambda}}| > 0.6$  and  $p_T < 0.12$ , ( $p_T$ ? or  $q_T$ ?) are applied. Furthermore the rapidity range (|y| (not  $|\eta|$ ?)) less than 0.5 is selected for comparing directly with  $\Lambda$  results. The final ranges of the criteria are summarized in Table 1.

## 3.1 Signal extraction

The  $\Sigma^0 + \overline{\Sigma}^0$  signals were extracted from invariant-mass distributions in each  $p_{\rm T}$ -bin of  $\Sigma^0$  for the range of 1.1 up to 8 GeV/c. For the estimates of raw yield of the signal, a Gaussian function added to a third-order polynomial is applied to describe the signal and background for the range of 1.160  $< M_{\Lambda\gamma} < 1.230$  GeV/ $c^2$  in each  $p_{\rm T}$ -bin. Examples of invariant mass distribution are presented in Fig. 1 for two different  $p_{\rm T}$ -bins.

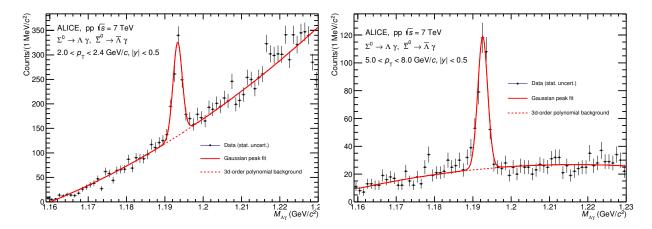

Fig. 1: Invariant mass distributions of  $\Lambda \gamma$  and  $\bar{\Lambda} \gamma$  pairs in  $p_T$  bins 2.0 - 2.4 and 5.0 - 8.0 GeV/c. The solid and dashed curves indicate a fit to the data using a third-order polynomial function with and without a Gaussian peak for the signal and background description, respectively.

The mean value  $(M_{\Lambda\gamma}=1192.94\pm0.035 MeV/c^2)$  of the  $\Sigma^0+\overline{\Sigma}^0$  invariant masses from the fit results in all  $p_{\rm T}$ -bins agrees well to the PDG value [1]:  $1192.642\pm0.024~{\rm MeV/c^2}$ . The standard deviations of the  $\Sigma^0$  signals extracted from the fits to data are about 2.2 MeV for  $1.1 < p_{\rm T} < 1.6~{\rm GeV/c}$  and about 1.2 MeV for  $p_{\rm T} > 2~{\rm GeV/c}$ , which are in a good agreement with the ones estimated by the fits to the simulated distributions. (How about then between  $1.6-2~{\rm GeV/c}$ ?) The increase of the width at low  $p_{\rm T}$  is mainly due to the low-energy photons.

The raw yield is obtained by integrating the Gaussian signal function in the region  $\pm 3$  standard deviation in each  $p_T$  bin. The statistical uncertainties on the raw yields range between 3-6%. The different approaches with various signal and background estimations and the calculations of  $\Sigma^0$  yields are discussed for the systematic uncertainties in section 3.3.

## 3.2 Corrections and normalization

By using the PYTHIA6 Perugia-2011 event generator [3] and the GEANT 3.21 package [20], the  $\Sigma^0$  signals are counted in each  $p_T$  from a generated sample of about 542 million MB pp events, and the correction factors  $(A \times \varepsilon)$  are estimated from the ratio between the number of reconstructed and generated  $\Sigma^0$  hyperons in the same  $p_T$  and rapidity interval, also with taking account the vertex reconstruction efficiency.? The  $p_T$  distribution of correction factors multiplied by branching ratios (B.R.) for  $\Sigma^0$  is shown in Fig. 2. The correction factors for  $\Sigma^0$  and  $\overline{\Sigma^0}$  are checked, respectively, and are consistent between each other in the measured  $p_T$ -interval between 1.1 and 8 GeV/c. Raw yields are thus corrected for the geometrical acceptance and the reconstruction efficiency  $(A \times \varepsilon)$  of the detector with taking into account the branching ratio of  $\Lambda$  decay.

The MB spectrum was normalized to the number of  $N_{norm}$  events after applying the correction factors for trigger efficiency and event selection including primary vertex reconstruction and rejection of pileup events It was done analogous to the approach implemented in PCM package which was already used in several publications of ALICE [12, 14]. All those corrections result in a total scaling factor of 0.922 for the calculation of the total number of events used in Eq. 3.

The MB spectrum was normalized to the number of  $N_{norm}$  events after applying the correction factors for trigger efficiency and event selection including primary vertex reconstruction and rejection of pileup

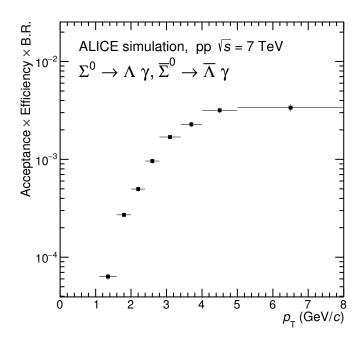

Fig. 2: The geometrical acceptance and the reconstruction efficiency  $(A \times \varepsilon)$  multiplied by B.R. for  $\Sigma^0$  in |y| < 0.5 for MB events, obtained with PYTHIA6 Perugia-2011 event generator [3]  $\overline{\Sigma^0}$  must be removed in the plot, since you say,  $\Sigma^0$  and  $\overline{\Sigma^0}$  are separately done and checked its consistency!). Only statistical uncertainties are shown.

events. The yield of  $\Sigma^0$  as a function of  $p_T$  is after background subtraction  $N^{\Sigma^0}$ :

$$\frac{d^2N}{\mathrm{dp_T}\mathrm{dy}} = \frac{1}{N_{MB}} \frac{N^{\Sigma^0}}{\Delta y \Delta p_{\mathrm{T}}} \frac{f_{vtx} \times f_{inel}}{A\varepsilon},\tag{1}$$

```
where N_{MB} = N_{in} - N_{OfflineTrigger} - trigger hits in either of two VZERO detectors,
184
    (Please specify what are N_{in}, NOfflinetriggers . Do you subtract also trigger hits in either of two VZERO detector??)
185
    the factor f_{vtx} (what is the value?) is the fraction of triggered events for which a good primary vertex is
    found, f_{inel} is the fraction of inelastic collisions that fulfill the trigger conditions. It was done analogous
187
    to the approach implemented in PCM package which was already used in several publications of AL-
188
    ICE [12, 14]. All those corrections result in a total scaling factor of 0.922 for the calculation of the total
189
    number of events used in Eq. 3.
190
    Question: in [12], MB_{OR} = INEL = at least one hit at SPD OR one of V0s
191
    NSD = an additional condition of coincidence of two VOs = MB_{AND}
192
    What was used? MB_{OR} or MB_{AND}?
193
    MB_{AND}/MB_{OR} = 0.873 in [10, 13] f_{inel} = trigger efficiency for INEL = 87%, f_{vtx} = vertex reconstruction
    within \pm 10cm = 88%
195
    What is then N_{in} and N_{offilinetrigger}? Nowhere I can find it.
196
    what is the relation between N_{norm} and N_{MB}?
197
```

## 3.3 Systematic uncertainties

198

The total  $\Sigma^0$  systematic uncertainty is determined by four general sources:

$$\sigma_{syst} = \sqrt{\sigma_{\gamma}^2 + \sigma_{\Lambda}^2 + \sigma_{\Sigma^0}^2 + \sigma_{mat}^2},$$
 (2)

where  $\sigma_{\gamma}$  and  $\sigma_{\Lambda}$  are the relative systematic uncertainties for the photon  $(\gamma)$  and  $\Lambda$   $(\bar{\Lambda})$  selections for the 200  $\Sigma^0$  ( $\overline{\Sigma^0}$ ) resonance, respectively, while  $\sigma_{\Sigma^0}$  and  $\sigma_{mat}$  are the systematic uncertainty due to the extraction 201 of  $\Sigma^0 + \overline{\Sigma^0}$  signals and the limited knowledge of the material budget for the conversion photon, relatively. 202 As two V0s for reconstruction of  $\Sigma^0 + \overline{\Sigma^0}$  resonances are independently analyzed with the photon con-203 version  $(\gamma \to e^+ e^-)$  and the weak decay  $(\Lambda \to p + \pi^-)$  and  $\overline{\Lambda} \to \overline{p} + \pi^+$ , the corresponding systematic 204 uncertainties are fully independent. Note, that quite low yield of the detected  $\Sigma^0 + \overline{\Sigma^0}$  limits the possi-205 bility of the extraction of several components of the systematic uncertainties which were investigated in 206 stand-alone analysis of  $\Lambda$  and isolated photon production with much larger statistics. (Do we need this 207 argument? For what?) 208

The main sources of systematic uncertainties for  $\Lambda$  selection are following: the pointing angle  $\Theta$ ,  $VO_{\Lambda}$  position, DCA between the  $\Lambda$  decay products, the ratio of the number of the reconstructed to the findable TPC clusters and, the difference between the proper lifetimes estimated from the difference  $L\frac{m^{\Lambda}-m^{K_{S}^{0}}}{p}$ , where L is defined as the distance between primary and  $VO^{\Lambda}$  vertex and p is its momentum. (What is it? It was not mentioned before at all! The uncertainties of PID of daughter particles MUST be included, instead.) The relative systematic uncertainties estimated in this analysis for the  $\Lambda$  identification vary between 3 to 11 % depending  $p_{T}$ , see Table 2, and are consistent with the ones estimated for  $\Lambda$  results in [5, 18].

The main source of the photon reconstruction uncertainty for PCM is determined by the identification of  $V0^{\gamma}$ . The uncertainty of identification of  $e^+$  and  $e^-$  tracks is estimated with varying the restrictions of  $\sigma_e$  in the TPC relative to the nominal dE/dx, and the contamination criteria ( $\sigma_{\pi,K}$ ) of pions and kaons [2]. The limits of the accepted  $V0^{\gamma}$  were also varied to evaluate its stability. The contribution of photon selection systematic uncertainty varies 4 to 12 % also depending  $p_T$ .

The systematic uncertainty of  $\Sigma^0$  + $\overline{\Sigma^0}$  yield extraction is estimated by varying the conditions of the background subtraction and raw-yield calculation of the invariant mass peaks shown in Fig. 1. The various combinations of the signal and the background distributions estimated by a mixed-event ( $e^+e^-$  pairs from different events) and a second-order polynomial, and the bin-counting method are applied for the for raw-yield extraction. The systematic uncertainties of raw-yield extraction range 2 to 10.5 %.

All systematic uncertainties are summarized in Table 2 for all  $p_{\rm T}$ , and the mean value of the total systematic uncertainty averaged over all  $p_{\rm T}$ -bins is 11.84 %.

$\sigma_{\Lambda}$	3 - 11 %
$\sigma_{\gamma}$	4 - 12 %
$\sigma_{\!\Sigma^0}$	2 - 10.5 %
Material budget	4.5 %
Total %	8 - 17

**Table 2:** Systematic uncertainties in  $\Sigma^0$  yield. The single valued uncertainties are  $p_T$  independent. Values given in ranges correspond to the minimum and maximum uncertainties.

### 4 Results and discussion

230

### 4.1 Transverse momentum spectrum

The corrected yield at mid-rapidity (dN/dy) of  $(\Sigma^0 + \overline{\Sigma^0})/2$  per event in  $p_T$  produced from inelastic pp collisions at 7 TeV is shown in Fig. 3. The measurements span the  $p_T$  range is from to 1.1 to 8 GeV/c. It was checked that the spectra obtained separately for  $\Sigma^0$  and  $\overline{\Sigma^0}$  are equal inside the uncertainties.

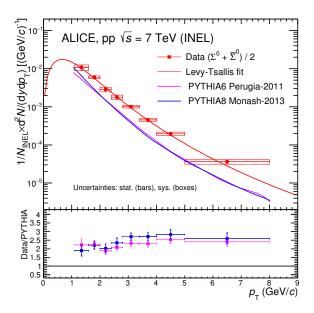

Fig. 3: (Top panel) Transverse momentum spectrum of  $(\Sigma^0 + \overline{\Sigma^0})/2$  in the rapidity range |y| < 0.5. Statistical (bars) and systematic (boxes) uncertainties are included. The solid line represents Lévy-Tsallis fit, the dashed and dot-dashed lines (The figure must be updated for w/b (no color)) represents the spectrum from PYTHIA6 Perugia-2011 [3] and PYTHIA-8 Monash-2013 [21] generators. (Bottom panel) Ratio of  $(\Sigma^0 + \overline{\Sigma^0})/2$  yield to the simulated ones for each generator in  $p_T$ .

The spectra are fitted with a Lévy-Tsallis function [22],

$$\frac{\mathrm{d}^2 N}{\mathrm{d}p_{\mathrm{T}}\mathrm{d}y} = p_{\mathrm{T}} \frac{\mathrm{d}N}{\mathrm{d}y} \frac{(n-1)(n-2)}{nC[nC + m_0(n-2)]} \left[ 1 + \frac{\sqrt{p_{\mathrm{T}}^2 + m_0^2 - m_0}}{nC} \right]^{-n},\tag{3}$$

where  $m_0$  is the PDG value of  $m_{\Sigma^0}$  [1]. Free parameter of the fit are the n, C and dN/dy, which represents the particle yield per unit of rapidity. This fit function is widely used to describe all identified particle spectra in pp collisions[18, 23, 24], and to extract the integrated total yield for all  $p_T$ .

Finally, the integrated yield at mid-rapidity for  $\Sigma^0$  of  $dN/dy = 0.0256 \pm 0.0083_{(total)} = 0.0256 \pm 0.0038_{(stat)} \pm 0.0047_{(syst)} \pm 0.0057_{(extrap)}$  is obtained from the data for measured range  $(p_T > 1.1 \text{ GeV/c})$  and the Lévy-Tsallis fit for unmeasured range  $(p_T < 1.1 \text{ GeV/c})$  of Fig. 3. The uncertainty (not shown (why?)) related to the overall normalization to inelastic events (or cross section) is fully correlated (with what?) and it amounts to +7.3% and -3.5% (+6.2% and -3.0%?) [23, 25]. The value of the mean  $\langle p_T \rangle$  of  $\Sigma^0$  was taken from the result of the fit without the uncertainty on material budget (why? What is then with  $\sigma_{mat}$  as shown in Table ??? Isn't it included to the  $\sigma_{syst}$ ?):  $\langle p_T \rangle = 1.161 \pm 0.085 (\pm 0.076_{stat} \pm 0.038_{syst})$ .

The values of dN/dy and  $\langle p_T \rangle$  were calculated by using the experimental spectrum in the measured  $p_T$ -range and the Lévy-Tsallis fit function outside of the measured  $p_T$ -range. Note that the fraction of the fit-function in the unmeasured  $p_T$  region between 0 and 1.1 GeV, i.e. from the low- $p_T$  extrapolation to the total dN/dy is quite significant and equal to 0.58 from Lévy-Tsallis fit and 0.57 from Boltzmann-Gibbs Blast-Wave fit [26]. The uncertainty of the yield due to extrapolation to the unmeasured  $p_T$ -range was calculated by varying of the fit functions and is included as an independent source of the total uncertainty. The  $m_T$ -exponential,  $p_T$ -exponential, Fermi-Dirac, Boltzmann, Bose-Einstein Blast-Wave and Bose-Einstein fits [27, 28] are applied from the region of  $p_T$  = 0 up to 4.0 GeV/c, where almost full statistics is presented. The weighted difference, with the weight corresponding to the probability of the fit, is used for the estimate of extrapolation uncertainty. (Fit functions are differently weighted? Why? Do we need this comment?) The fraction from the high- $p_T$  extrapolation is found to be negligible.

The transverse momentum spectra of  $(\Sigma^0 + \overline{\Sigma^0})/2$  is compared to both the Perugia-2011 tune of the PYTHIA generator [3] and Monash-2013 tune [21], see Fig. 3. One can see that the applied generators significantly underestimate the dN/dy in  $p_T$ , accordingly the overall production of  $\Sigma^0$  and  $\overline{\Sigma^0}$ . Note that similar one is concluded from the comparison of Λ production at ALICE with PYTHIA Perugia-2011 event generator [18, 19]. (THERMUS MUST be compared and discussed!)

The ratios of  $(\Sigma^0 + \overline{\Sigma^0})/2\Lambda$  from data [29], PYTHIA 6-Perugia 2011 [3] and PYTHIA 8-Monash 2013 [21] are presented as a function of  $p_T$  in Fig. 4. Note the trend of the monotonic increase of the ratio from data with  $p_{\rm T}$ , while the ratios from both generators do show weird or practically no  $p_{\rm T}$ -dependence. Despite of large uncertainties,  $\Sigma^0$  in low  $p_T$  is significantly suppressed relative to  $\Lambda$ . This ratio of  $\Sigma^0$  to  $\Lambda$  in high  $p_{\rm T}$  in the generators is abnormally suppressed due to underestimated  $\Sigma^0$  and overestimated  $\Lambda$ -yields relative to the data, as shown in the previous section 4.1 and [29]. (THERMUS MUST be compared and discussed!)

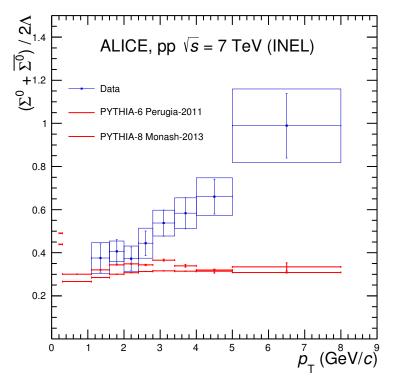

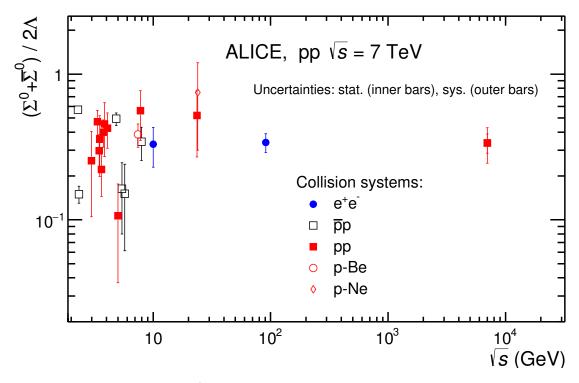

Fig. 4: The differential ratios of  $\Sigma^0 + \overline{\Sigma^0}$  )/2 to  $\Lambda$  from data [29] in the same bins of  $p_T$  (blue points). (The ratio (line) from the Lévy-Tsallis curves based on  $\Sigma^0$  and  $\Lambda$  data is drawn in full range of  $p_T$ . ???) The red points indicate the same ratios from PYTHIA 6-Perugia 2011 and magenta points from PYTHIA 8-Monash 2013, respectively.

The integrated yield ratios of  $\Sigma^0$  to  $\Lambda$  from various collision systems at different enrgies are shown as a function of  $\sqrt{s}$  in Fig. 5. The integrated yield ratio measured with ALICE in pp collisions at  $\sqrt{s}$ 7 TeV is  $0.337 \pm 0.111$ (total) =  $0.337 \pm 0.051$ (stat)  $\pm 0.099$ (syst), where the extrapolation uncertainty is included into the systematic error. While yields of  $\Sigma^0$  have been measured in many different collision systems at low and intermediate energies, there exist only few results in high energy collisions including the ALICE result. The relatively new and more precise COSY-TOF pp data from Ref. [30, 31] see Fig. 5, have been published as the function of  $\varepsilon = \sqrt{s} - (m_p + m_K + m_{\Lambda, \Sigma^0})$  and correspond to  $\sqrt{s} \approx 2$ GeV/c. The cross section ratio  $\frac{\Sigma^0}{\Lambda} \approx 0.45 \pm 0.05$ . The STAR detector reconstructed the electromagnetic decay ( $\Sigma^0 \to \Lambda + \gamma$ ) via the weak decay of the

 $\Lambda \to p + \pi^-$  and  $\gamma$  conversions into  $e^+e^-$  pairs in the detector material [31, 32]. The cross section ratio  $\Sigma^0/\Lambda = 0.16^{+0.41}_{-0.09}$  was thus obtained in minimum bias 0.2 TeV d+Au collisions. Note that STAR data with so large errors were published only in a conference proceeding [32] by the collaboration due to the limited statistics. Note: The STAR result is, however, also cited in the regular paper [31] The most precise data are from L3 experiment [33, 34], where both  $\Sigma^0$  and  $\Lambda$  have been measured as a product of Z boson decays, as shown in Fig. 5, where  $\Sigma^0/\Lambda \approx 0.33 \pm 0.03$  (This value is hardly confirmed from the two papers [33, 34], and the phenomenology paper [31] DID NOT cite this L3 value!). These data in wide range of  $\sqrt{s}$  support the convergence of the  $\Sigma^0/\Lambda$  -ratio as expected by [31]. High energy nuclear collisions are of particular interest for the final state interactions [31] and the possibility of measuring isospin degeneracy factors from  $\Sigma^0$  and  $\Lambda$  yields and of opening new channels of hyperon production via partonic degrees of freedom [35].

**Fig. 5:** Energy dependence of  $\Sigma^0$  to  $\Lambda$  cross section ratio Which points to include - to be discussed.

#### 5 Conclusions

In summary,  $\Sigma^0$  ( $\overline{\Sigma^0}$ ) hyperons produced in pp collisions at  $\sqrt{s}=7$  TeV are successfully reconstructed via electromagnetic decay to  $\Lambda$  ( $\overline{\Lambda}$ ) and  $\gamma$ . The  $p_T$  distribution of ( $\Sigma^0 + \overline{\Sigma^0}$ )/2 is obtained and compared with two different versions of PYTHIA generators, which both significantly underestimate the differential yields. So far no generator is found to explain the  $\Sigma^0$  yield produced in pp collisions at  $\sqrt{s}=7$  TeV. Furthermore the differential yield ratios of  $\Sigma^0$  to  $\Lambda$  from data and the generators are compared and the significant underestimates of  $\Sigma^0$  / $\Lambda$  in both generators are observed in high  $p_T$ .

The integrated yield ratio measured in pp collisions at  $\sqrt{s} = 7$  TeV is  $(\Sigma^0 + \overline{\Sigma^0})/2\Lambda = 0.337 \pm 0.111$  (total) =  $0.337 \pm 0.051$  (stat)  $\pm 0.099$  (syst), where the systematic uncertainty includes the Lévy-Tsallis fits of  $\Sigma^0$  and  $\Lambda$  spectra extrapolated to the unmeasured low  $p_T$ . So far this  $(\Sigma^0 + \overline{\Sigma^0})/2\Lambda$  at the highest energy collision system uniquely contributes to consistency of an isospin degeneracy factor, 1/3 with the same ratios in various collisions at different energies from world-wide experiments. The current measurement represents a relevant baseline for further investigation in p-Pb and Pb-Pb collisions.
